Fifty sleeps of 3.2 ms took 756 ms, and that is why I deleted my RTP pacer

Fifty consecutive 3.2 ms sleeps consumed 756.7 ms of wall clock. The pacer was right in theory and destructive in practice, because Windows rounds every short sleep up to 15.6 ms.

20 AUG 2026 · 5 MIN READ

I built a self-hosted remote desktop for Windows that streams the screen to a browser tab over WebRTC. It works. The part worth writing down is a fix I was confident about, shipped, measured, and then removed.

The symptom

Round-trip time measured in the browser swung between 7 ms and 7000 ms. The path was Tailscale direct, 2 ms raw RTT, no packet loss. Server-side logs insisted capture and delivery were both a steady 30 fps.

Two instruments disagreeing by three orders of magnitude usually means one of them is measuring something other than what its name says.

The hypothesis that was right

aiortc encodes H.264 synchronously inside the same asyncio event loop that runs ICE, DTLS, RTP send and the input data channel. It also ships no RTP send pacer. That is confirmed in aiortc discussion #965 and visible by reading `rtcrtpsender.py`: packets for a frame leave in a tight `for` loop with nothing between them.

A keyframe at 3 Mbps is 150 or more RTP packets. Emitting 150 packets back to back inside the event loop starves ICE heartbeats for the duration. Starved heartbeats explain a 7-second RTT reading much better than a 2 ms network does.

So far so good. The diagnosis held up.

The fix that made it worse

I wrote a leaky-bucket pacer. One `asyncio.sleep(9600 / bitrate)` between packets, which at 3 Mbps is about 3.2 ms. Standard approach, roughly what libwebrtc does.

Delivered frame rate fell from a bad 8 fps to a much worse 2 or 3 fps. Keyframes stalled for most of a second. Per-frame `pipeline_gap` climbed from 70 ms to somewhere between 222 and 504 ms.

I had made the thing I was fixing about five times worse.

What was actually happening

Windows keeps its default system timer granularity near 15.6 ms. Every timer-backed wait rounds up to that tick. `asyncio.sleep(0.0032)` does not sleep for 3.2 ms on stock Windows. It sleeps for about 15.

I timed it directly rather than reasoning about it:

```
fifty consecutive asyncio.sleep(3.2ms) calls -> 756.7 ms of wall
clock
```

Fifty sleeps that should have cost 160 ms cost 756.7 ms. A 150-packet keyframe was therefore locked out of the send path for roughly three quarters of a second, every single time a keyframe went out.

The pacer was solving a congested-WAN problem that a 2 ms tailnet link does not have, and paying for it with a Windows timer bill I had not measured.

What replaced it

`install_send_pacer()` is now a documented no-op. It keeps exactly one line of the original implementation:

```
winmm.timeBeginPeriod(1)
```

That single call drops system timer granularity from 15.6 ms to 1 ms process-wide. It does nothing for my deleted pacer, because the pacer is gone. What it does is make every *other* short sleep inside aiortc accurate:

RTCP timing, retransmit scheduling, every internal wait that was silently rounding up to 15 ms and that I had never thought to look at.

The keyframe burst problem got solved the boring way instead, by raising GOP from 60 to 120 frames. Half as many keyframes, half as many bursts.

The other bug, which was a real bug

While in there I found something that was unambiguously broken. aiortc fragments the H.264 bitstream at fixed 1200-byte offsets without looking for NAL start codes. A keyframe carrying SPS, PPS and an IDR slice together gets cut mid-NAL and arrives corrupt.

The browser responds to a corrupt keyframe with a PLI. The encoder produces another keyframe. That one gets fragmented identically and corrupts identically. It is a stable loop that looks like a network problem and is not one.

`_nal_aware_split_bitstream` cuts on Annex-B start codes first and leaves MTU fragmentation to FU-A, where it belongs.

I also swapped libx264 for `h264_nvenc` with `preset=p1`, `tune=ull`, `rc-lookahead=0`, `surfaces=2`. Measured in isolation, that encodes a 1080p frame in 10.8 ms.

Where it actually stands

The last measured session captured at 30.0 fps and delivered 8.6 fps to the browser, with 42.5 ms spent inside `recv()` and a 70.4 ms pipeline gap per frame. It is watchable, input feels close to immediate at lower resolutions, and 1080p30 is not there. The remaining bottleneck is the Python RTP send path, which is why there is now a second host built on GStreamer `webrtcbin` with a zero-copy D3D11 capture and encode path.

There is also no authentication of any kind. Anyone who reaches the port gets keyboard and mouse. I run it inside a tailnet and that tailnet is the entire security model.

The thing I would say in an interview

The correct diagnosis and the correct fix are not the same artifact, and being right about the first one bought me nothing.

I was right that aiortc has no pacer. I was right that unpaced bursts starve the event loop. The pacer was still the wrong move, and I would not have known that from reading more about WebRTC congestion control, because the failure was not in WebRTC at all. It was in what `sleep` means on the operating system I happened to be running.

The measurement that mattered was never on the network. It was on the clock the sleep call was using.

Code, including the deleted pacer left in as a documented no-op with the reasoning attached: https://github.com/Fabi-SPL/remote-desktop
